### Biography of Writer

The writer was born in Savannah, Georgia, on May 29, 1916. He attended public school in Savannah and West Palm Beach, Florida, and was graduated from the Alabama Polytechnic Institute in 1938, receiving the degree of Bachelor of Science in Chemical Engineering.

After graduation he was employed by the Southern Cement Company of Birmingham, Alabama, and Joseph E. Seagram and Sons, Inc., of Lawrenceburg, Indiana.

He was commissioned an Ensign in the United States Naval Reserve in 1942, and was on duty in Washington, D. C., for most of the late war, being promoted to Lieutenant in 1944.

Biography of William

was born at Port in Louisiana, on May 28,

1916. He attended public school in New Orleans and was a member of the Junior League. He was graduated from the Louisiana State University in 1938, receiving the degree of Bachelor of Science in Mechanical Engineering.

After graduation he was employed by the Southern Railway Company of Birmingham, Alabama, and later by the Alabama and Georgia Railway and Power Company, Birmingham, Alabama.

He was commissioned as Ensign in the United States Navy

active in 1942, and was on duty in England, France, and Italy from 1942 to 1945. He was promoted to Lieutenant in 1944.

## The Stabilization of Smokeless Powder

### Manufacture of Smokeless Powder

The smokeless powder used as a propellant in the armed forces of the United States is normally a "single-base" nitrocellulose powder made by colloidizing nitrocellulose containing about 12.6 per cent of nitrogen.

The nitrocellulose, known as "pyrocellulose", is made by nitrating either purified cotton linters or special alpha-cellulose prepared from spruce pulp. The material is nitrated in batches of about forty pounds each, with mixed acid of about the following composition:

	Per Cent
Sulfuric Acid	63
Nitric Acid	21
Water	16

A charge of almost 2000 pounds of acid is used for each batch of cellulose. The nitration usually takes about twenty-five minutes; the temperature of the acid being kept almost constant at 30-34° C. by cooling coils in the nitrator. The spent acids are then removed from the nitrocellulose by a centrifugal directly below the nitrator, and are fortified for reuse or sent to the recovery plant.

The partially dry nitrocellulose is forked through an opening in the center of the centrifuge into a trough containing a stream of water.

The drowned crude nitrocellulose contains some sulfate esters of cellulose, and some nitrate esters of oxycellulose

Manufacture of Nitrocellulose Powder

The nitrocellulose powder used as a propellant in the

armed forces of the United States is normally a "single-base"

nitrocellulose powder made by solubilizing nitrocellulose con-

taining about 22.5 per cent of nitrogen.

The nitrocellulose, known as "pyrocellulose", is

made by nitrating either purified cotton linters or special alphas-

cellulose prepared from spruce pulp. The material is nitrated in

batches of about forty pounds each, with mixed acid of about the

following composition:

Per cent

65  
32  
3  
10

Nitric Acid  
Sulfuric Acid  
Water

A charge of about 3000 pounds of acid is used for each batch of  
cellulose. The nitrator usually takes about twenty-five minutes;  
the temperature of the acid being kept almost constant at 70-75° F.  
by cooling coils in the nitrator. The spent acids are then removed  
from the nitrocellulose by a centrifugal directly below the nitrator  
and are furnished for reuse or sent to the recovery plant.

The partially dry nitrocellulose is forced through

an opening in the center of the centrifuge into a trough contain-  
ing a stream of water.

The brown crude nitrocellulose contains some

soluble esters of cellulose, and some nitrate esters of pyrocellulose

and of hydrocellulose; all of these impurities are less stable than nitrocellulose itself. They are all capable of being hydrolyzed by long boiling with slightly acidified water. To remove these impurities, the nitrocellulose is subjected to several stabilizing processes.

The first of these, known as "sour boiling", consists of a long series of boilings with water containing from 0.25 per cent to 0.50 per cent of sulfuric acid. The usual procedure is to boil a total of forty hours with at least four changes of water.

Even after the continued boiling, the fibers of nitrocellulose, which still have the hollow structure of the original cellulose fibers, usually retain some acid. To remove this acid, the fibers are "pulped". This is accomplished by a beater, a Jordan mill, or a combination of the two. Most of the acid contained in the fiber is released when the fibers are broken up, and is neutralized by a weak solution of sodium carbonate added during the pulping.

The pulped fibers still contain traces of adsorbed acid and of unhydrolyzed unstable esters; these are removed by "poaching". The pulp is boiled again repeatedly with dilute sodium carbonate and then with water, and finally is washed at least eight times by thorough agitation with water; each time at least 40 per cent of the liquid is decanted.

After washing, the material is screened to give finished pyrocellulose. If the pyrocellulose is to be converted

and of organic nitrogen; all of these are lost while  
then nitrocellulose itself. They are all capable of being  
hydrolyzed by long boiling with slightly acidulated water. To  
remove these impurities, the nitrocellulose is subjected to  
several additional processes.

The first of these, known as "hot boiling", con-  
sists of a long series of boilings with water containing from  
0.25 per cent to 0.50 per cent of sulfuric acid. The usual pro-  
cedure is to boil a total of forty hours with at least four changes  
of water.

After the continued boiling, the fibers of  
nitrocellulose, which still have the hollow structure of the  
original cellulose fibers, usually retain some acid. To remove  
this acid, the fibers are "washed". This is accomplished by a  
beater, a leather mill, or a combination of the two. Most of the  
acid contained in the fiber is released when the fibers are broken  
up, and is neutralized by a weak solution of sodium carbonate added  
during the washing.

The washed fibers still contain traces of absorbed  
acid and of unhydrolyzed unstable esters; these are removed by  
"soaping". The pulp is boiled again repeatedly with dilute  
sodium carbonate and then with water, and finally is washed at  
least eight times by thorough agitation with water; each time at  
least 10 per cent of the liquid is decanted.  
After washing, the material is returned to give  
finished pyrocellulose. If the pyrocellulose is to be converted

to smokeless powder in the same establishment, it is pumped to the powder plant as a slurry. If it is to be shipped, it is dried to a water content of about 25 per cent and packed.

The first process in the actual conversion of pyrocellulose to smokeless powder is dehydration. The slurry is filtered by a continuous filter of the Oliver type and the pulp placed in a hydraulic press, where most of the water is removed by the application, for a short time, of a pressure of about 250 pounds per square inch. The pressure is released, and alcohol, in an amount at least equal to the dry weight of the nitrocellulose, is forced into the mass by a pump. The pressure is then increased to about 3500 pounds per square inch, pressing the material into a cylindrical block. The process is controlled so that the product retains just enough alcohol for the colloidizing operation.

The compressed block is placed in a kneading machine and broken up by hand. This machine is similar to a bread kneading machine used in large bakeries. Then ether is added rapidly and mixed in as fast as possible. Enough ether is added so that the final liquid consists of about one part by weight of alcohol and two parts by weight of ether, the total weight of liquid being approximately equal to that of the nitrocellulose. The stabilizer is mixed with the ether before adding to the powder.

After mixing, the powder looks like brown sugar. It is soft enough to be deformed by hand, and sticks together when squeezed.

to increase weight in the same relationship, it is placed in  
the powder plant as a slurry. If it is to be dried, it is dried  
to a water content of about 15 per cent and packed.

The first process is the initial conversion of  
pyrotechnics to ammonium powder in dry form. The slurry is  
filtered by a continuous filter of the Oliver type and the pulp  
placed in a hydraulic press, where most of the water is removed  
by the application, for a short time, of a pressure of about 350  
pounds per square inch. The pressure is released, and alcohol,  
in an amount at least equal to the dry weight of the nitrocellulose,  
is forced into the mass by a pump. The pressure is then  
increased to about 3500 pounds per square inch, pressing the  
material into a cylindrical block. The process is controlled so  
that the product retains just enough alcohol for the softening  
operation.

The compressed block is placed in a kneading  
machine and broken up by hand. This machine is similar to a bread  
kneading machine used in large bakeries. Then ether is added  
rapidly and mixed in as fast as possible. Enough ether is added  
so that the final liquid consists of about one part by weight of  
alcohol and two parts by weight of ether, the total weight of  
liquid being approximately equal to that of the nitrocellulose.  
The stabilizer is mixed with the ether before adding to the  
powder.

After mixing, the powder looks like brown sugar.  
It is soft enough to be deformed by hand, and sticks together when  
pressed.

The incompletely colloidized material from the mixer is pressed into a compact cylindrical mass in a preliminary or "blocking" press, which exerts a pressure of about 3500 pounds per square inch. This block is then placed in a "macaroni press", from which it is forced through several small holes, to emerge as strings that look like macaroni.

These strings are placed in a final blocking press, which may be the same press used for preliminary blocking, and reformed into a cylinder. In this operation the pressure is maintained for one or two minutes; this application of pressure completes the colloidizing.

The block from the final press is placed into the graining press, from which it is forced through a die to form a long tube containing either one or seven perforations. This tube is cut into the proper lengths to form the powder grains. The "green" powder from this operation still retains a considerable amount of ether and alcohol, most of which must be removed.

The green powder is dried to the desired final solvent content. Complete elimination of solvent is undesirable, because completely dry powder burns too fast for satisfactory use as a propellant, and also because completely dry powder is so hygroscopic that it changes rapidly in moisture content and in ballistic properties when exposed to air.

The solvent is recovered from the powder by either of two methods. In the older method the powder is placed in a

[illegible]

closed system and air, at about 60° C., is circulated through it. The warm air removes most of the solvent from the powder, and the solvent is then removed from the air by cooling or by scrubbing with a suitable solvent. The process requires careful control, since the powder, on drying, tends to form a surface skin through which further passage of the solvent from the interior is very slow.

The newer method of solvent recovery is known as "water drying". In this process, warm water is used instead of air. The water causes the formation of microscopic cracks and pores on the surface of the powder, thus preventing the formation of the surface skin and allowing the solvent to pass from the interior of the grain into the water. The alcohol and ether pass into the water because they are more soluble in water than in powder. Thus the process is really one of extraction. In addition to more effective drying, this process reduces the warping customarily suffered by air-dried powder.

When the solvent has been sufficiently removed, the powder is taken out of the water, and the surface water is removed in a dryer. The finished powder contains about 3 per cent of volatile matter in the interior of the grain and about 1 per cent of surface water. Most of this is actually contained in the microscopic cracks and pores on the surface.

The amount of water held on the surface is extremely important in affecting the stability of the powder. The amount of water should be such that there is little tendency

closed system and air, at about 100 mm. Hg. The air is removed from the system, and the solvent is then removed from the air by passing it through a suitable solvent, the solvent being then removed from the powder, on drying, to form a surface film through which further passage of the solvent from the interior is very slow.

The newer method of solvent removal is known as

"water drying". In this process, warm water is used instead of air. The water causes the formation of microscopic cracks and pores on the surface of the powder, thus preventing the formation of the surface film and allowing the solvent to pass from the interior of the grain into the water. The alcohol and other pass into the water because they are more soluble in water than in powder. Thus the process is really one of extraction. In addition to more effective drying, this process reduces the warping substantially suffered by air-dried powder.

When the solvent has been sufficiently removed, the powder is taken out of the water, and the surface water is removed in a dryer. The finished powder contains about 3 per cent of volatile matter in the interior of the grain and about 1 per cent of surface water. Most of this is actually contained in the microscopic cracks and pores on the surface.

The amount of water held on the surface is

extremely important in affecting the stability of the powder. The amount of water should be such that there is little tendency

for the moisture to evaporate in dry weather or for the powder to take up water during humid weather.

After drying, the powder from several batches is blended to produce a large quantity of essentially uniform powder. Such a quantity is called a "lot". The powder from each lot is generally kept together and assigned to be used by the same ship or battery.

After blending, the powder is stored in metal-lined boxes sealed with rubber gaskets. Every effort is made to keep the containers watertight, to avoid the effects of changing humidity.

#### Stability of Smokeless Powder

Even pure nitrocellulose, in either the colloided or uncolloided state, tends to decompose slowly on standing, with the formation of nitric oxide and nitrogen dioxide. The rate of decomposition rises with the temperature; the reaction is accelerated by high humidity. In the presence of acid the rate of decomposition is very greatly increased. Nitrocellulose that has not been freed completely from sulfate esters of cellulose is much less stable than the thoroughly purified material. The sulfate esters hydrolyse more rapidly than the cellulose nitrate itself, and the traces of sulfuric acid set free by the hydrolysis catalyse the decomposition. The nitrate esters of hydrocellulose and oxycellulose also tend to make the powder unstable; they decompose readily to form oxides of nitrogen that can react with

any moisture present to form acids that catalyse the decomposition of the true nitrocellulose.

Although well purified nitrocellulose is rather stable and does not begin to break down readily at room temperature, a small amount of decomposition does take place within a relatively short period of time. The oxides of nitrogen produced by this decomposition attack the nitrocellulose very rapidly, causing further decomposition. Thus, if these oxides are not removed, the decomposition is "auto-catalytic" and its rate increases rapidly, causing considerable decomposition in a short time. For this reason there must be added to the smokeless powder some compound which will react with the oxides as fast as they are formed, tying them up as some compound which does not further the decomposition. Such an additional compound is called a stabilizer, and powder to which it has been added is said to be stabilized.

### Stabilizers

There are two important requirements for a good stabilizer in addition to the obvious one that it must react with the oxides of nitrogen formed by the decomposition of nitrocellulose.

First, neither it nor the product of its reaction with the oxides of nitrogen should react with the nitrocellulose. Thus the use of an alkali as a stabilizer is not feasible, because both the alkali and the nitrates and nitrites formed from it react very rapidly with nitrocellulose. (1)

any substance present in the solid that enters the reaction  
 then it is not a stabilizer.  
 Although all chemical reactions are reversible  
 and some are more reversible than others, a reaction  
 is called irreversible if the equilibrium lies so far to the right  
 that the concentration of the reactants is negligible.  
 The order of a reaction is the number of molecules of  
 the reactants that take part in the reaction. It is  
 determined by the rate of reaction. The order of a reaction  
 is not necessarily the same as the stoichiometric coefficients  
 in the balanced equation. For example, in the reaction  
 $2\text{H}_2\text{O}_2 \rightarrow 2\text{H}_2\text{O} + \text{O}_2$ , the order of reaction is 1, although  
 the stoichiometric coefficient of  $\text{H}_2\text{O}_2$  is 2.  
 The rate of a reaction is the change in concentration  
 of a reactant or product per unit time. It is usually  
 expressed in moles per liter per second. The rate of  
 a reaction is affected by temperature, concentration,  
 and the presence of a catalyst. The rate of a reaction  
 is also affected by the physical state of the reactants.  
 For example, the rate of a reaction is faster if the  
 reactants are in the same phase than if they are in  
 different phases. The rate of a reaction is also  
 affected by the surface area of the reactants. For  
 example, the rate of a reaction is faster if the  
 reactants are finely divided than if they are in large  
 pieces.

### Stabilizers

There are two important requirements for a good  
 stabilizer in addition to the obvious one that it must react with  
 the oxygen of nitrogen formed by the decomposition of nitrocellulose.  
 First, neither it nor the product of its reaction  
 with the oxygen of nitrogen should react with the nitrocellulose.  
 Then the use of an alkali as a stabilizer is not feasible, be-  
 cause both the alkali and the nitrate and nitrite formed from  
 it react very rapidly with nitrocellulose. (1)

Second, neither the stabilizer nor its products should destroy the homogeneity of the powder. Calcium carbonate, which is a good stabilizer for dynamite, cannot be used for smokeless powder because it is insoluble and remains as a finely divided solid in the powder. Urea, which otherwise is a very good stabilizer, cannot be used because it produces bubbles of nitrogen gas in the powder.

The stabilizer should also be relatively cheap, and both it and its products must be themselves stable.

Stabilizers have been used in smokeless powder ever since its first manufacture in France in 1884. The first substance used was amyl alcohol (2), which reacts with the oxides of nitrogen to form esters, amyl nitrite and amyl nitrate. These esters are in turn attacked by the oxides, and break down, releasing nitric and nitrous oxides, and at the same time the amyl radical is oxidised to valeric acid. The presence of valeric acid can readily be detected by its odor, and its presence was taken as evidence that the amyl alcohol was exhausted and the powder no longer stable. Since each molecule of amyl alcohol reacts with only one nitrogen, which it later gives up, amyl alcohol is a very poor stabilizer. Its use was abandoned, but not until two French warships had been destroyed by explosions attributed to spontaneous inflammation of the powder in their magazines. The Italians used aniline as a stabilizer, but since aniline itself attacks nitrocellulose, it makes a very poor stabilizer and its use was soon discontinued.

...and the use was soon discontinued.

By far the most important stabilizer is diphenylamine, which was used as early 1909 and is still the standard in most countries, including the United States.

The only substance which can compete with diphenylamine as a stabilizer is "Centralite", a trade name for any of several alkyl-substituted diphenyl ureas, the most usual being symmetrical diethyl diphenyl urea. However the centralites are used chiefly as solvents and coatings. In this paper diphenylamine and centralite will be discussed in detail, followed by a list of other compounds which have been used or proposed and a discussion of the comparative stabilization powers of the various compounds.

### Diphenylamine

Diphenylamine is by far the most important stabilizer for smokeless powder, although it is generally considered that centralite is actually a better stabilizer.

The qualities of diphenylamine as a stabilizer were first established by M. Marquoyrol in a series of researches lasting fifteen years (3). Samples of smokeless powder containing up to 10 per cent of diphenylamine were heated at five different temperatures for periods up to 4083 days, and samples were removed from time to time for analysis of the nitrogen content of the nitrocellulose. Up to that time it was generally considered that smokeless powder decomposed at a rapid and uncontrollable rate. Marquoyrol's tests established the fact that nitrocellulose is essentially stable and loses stability only

...the most important stabilizer is diphenylamine, which was used as early as 1911 and is still the standard in most countries, including the United States.

The only substance which can compete with diphenylamine as a stabilizer is "Centriol", a trade name for one of several alkyl-substituted diphenyl amines. The most usual being symmetrical dialkyl diphenyl amines. However, the stabilizers are used chiefly as solvents and scummers. In this paper diphenylamine and centriol will be discussed in detail, followed by a list of other compounds which have been used or proposed and a discussion of the comparative stabilizing powers of the various compounds.

### Diphenylamine

Diphenylamine is by far the most important stabilizer for smokeless powder, although it is generally considered that centriol is actually a better stabilizer. The qualities of diphenylamine as a stabilizer were first established by E. Knappey in a series of experiments lasting fifteen years (3). Samples of smokeless powder containing up to 10 per cent of diphenylamine were heated at five different temperatures for periods up to 4000 days, and samples were removed from time to time for analysis of the nitrogen content of the nitrocellulose. Up to that time it was generally considered that smokeless powder decomposed at a rapid and uncontrollable rate. Knappey's tests established the fact that nitrocellulose is essentially stable and loses stability only

when in contact with slight amounts of its decomposition products. He showed that the first reaction product of diphenylamine is diphenylnitrosamine, which is itself a better stabilizer than diphenylamine. This is due to the fact that nitrosamine is a gelatinizer for nitrocellulose, and remains intimately mixed with it, whereas diphenylamine does not. However at elevated temperatures the nitrosamine has very poor stabilizing power.

These tests also showed that the effect of temperature is very important on the action of a stabilizer, since some of the reaction products may themselves be unstable at certain temperatures. Therefore any test for stabilization should be run at at least two temperatures. These observations in regard to the effect of temperature were confirmed by other researchers (4) (5) who also found that the presence or absence of oxygen and the amount of moisture present in the powder also materially affected the results.

Marqueyrol and others have studied the derivatives of diphenylamine which cause powder to darken with age, and have concluded that they are due to impurities in the ether used in the powder or to the oxidizing action of the air during drying, and are not products of a reaction between diphenylamine and nitrocellulose or the oxides of nitrogen. (6) (7) (8). The principal oxidation product producing darkening is diphenyl dihydro phenazine.

The transformations undergone by diphenylamine as a result of the decomposition of the powder have been studied

[illegible]

by several investigators and seem to be fairly well established. The chief work in this field was done by Davis and Ashdown at M. I. T., working under a contract for the U. S. Army. (9) (10) They prepared all the compounds which might be expected to be formed by nitration of diphenylamine and devised color tests to indicate the presence of each of them, as well as methods of separating each from mixtures of one another and nitrocellulose. These separations and tests were applied to diphenylamine-stabilized powders in various stages of decomposition, the most advanced being a powder that had been giving off fumes for several months. These tests indicate that the reactions are as follows:

The first step in the synthesis of the polymer is the reaction of the monomer with the initiator. This reaction is exothermic and produces a radical intermediate. The radical intermediate then reacts with another monomer molecule to form a dimer radical. This process continues until the chain is terminated. The termination step can occur in several ways, such as recombination of two radicals or reaction with a termination agent. The resulting polymer is a linear chain of monomer units. The molecular weight of the polymer can be controlled by the concentration of the initiator and the reaction time. The polymerization process is sensitive to impurities and temperature.

The last product formed, 2-4-4' trinitrodiphenylamine, might be expected to undergo further nitration to the 2-4-2'-4' tetranitro compound, but rather exhaustive attempts to isolate this compound were not successful.

Becker and Hunold, (11), confirm the fact that the tetranitro product is not formed. They also isolated several more intermediate compounds. Their proposed reactions are as follows:

The first step in the mechanism is the formation of a radical cation from the starting material. This is followed by a series of electron transfer steps, which eventually lead to the formation of a dimer. The dimer is then subjected to further transformations, including the loss of a proton, to yield the final product. The overall reaction is a complex process involving multiple steps and intermediates.

Reaction

The two mechanisms lead to the same end product, a trinitro derivative. The fact that diphenylamine takes up three nitro groups per molecule is one of the reasons that the compound is such a good stabilizer.

Becker and Hunold also measured the relative time required for the formation of the various compounds from powder containing diphenylamine, which was kept at 100° C. The nitrosamine was detected even before heating, the mononitro compound after one day at the elevated temperature, the dinitro after two days and the trinitro after four days.

They also tested the stabilizing power of the various intermediates by preparing powders containing each of these compounds. The relative values were as might be expected, except that the last product, the trinitro compound, was a better stabilizer than the compounds immediately preceding it, the dinitro diphenylnitrosamines. Since neither of these actually takes up any more nitrogen, it is hard to see how either can act as a stabilizer. No explanation was offered.

There is some evidence that the reaction is not as simple as the above discussion might indicate. The effect of temperature has been largely ignored in both the above experiments, but other workers have found that the reaction is apparently different at different temperatures. It was found (12) that stabilized powders decomposed at a rate which was only one-fifth to one-sixth that of unstabilized powder at 50° C., but at 77.5° C. its reaction rate was one-third that of the unstabilized powder.

[illegible]

This would indicate either that the reactions are different at different temperatures, or that the method of testing is inaccurate. The low-temperature test may not indicate the true velocity of decomposition.

It was also found (13) that a catalyst was necessary to carry out the reaction between diphenylamine and oxides of nitrogen in the laboratory. Chlorides and copper salts were used as catalysts. It is supposed that the small amounts of copper salts present in smokeless powder from the various manufacturing containers act as catalyst when the reaction occurs in powder.

It has also been observed that the purity of the diphenylamine and of the nitrocellulose affect the stability.

(14) Powders made in 1912 with normally stabilized nitrocellulose and purified diphenylamine showed no loss of stability when tested after twenty years storage at room temperature, while powder manufactured during the first World War, using rapidly stabilized nitrocellulose and technical diphenylamine, showed marked losses of stability in fifteen years.

In this connection it is interesting to note that it is possible to restabilize powder with diphenylamine. The process (15) is performed by softening the powder in alcohol, without altering the grain size, and then re-impregnating with diphenylamine in alcohol solution.

Powder which has been stabilized with diphenylamine may be tested for stability and suitability for further use rather easily. A powder is considered unfit for further

[illegible][illegible][illegible][illegible]

was rather easily. A powder is considered unfit for further  
use may be tested for stability and suitability for further  
powder which has been stabilized with diphenyl-

storage if all of the diphenylamine and the diphenylnitrosamine have been exhausted. These compounds may be detected in an alcohol extract of the powder by simple color tests as follows:

If diphenylamine is present, a strip of filter paper on which an alcoholic extract of the powder has been allowed to dry is colored blue by a drop of ammonium persulfate. Also, if the extract contains diphenylamine it is colored blue by the addition of a few drops of a saturated solution of ammonium persulfate. Diphenylnitrosamine gives no color with ammonium persulfate, but imparts an intense blue color to a few milliliters of cold concentrated sulfuric acid.

#### Centralite

The first centralite was symmetrical dimethyl diphenyl urea. It was called centralite because it was developed at the Central War Laboratory in Germany. The ethyl compound, symmetrical diethyl diphenyl urea, usually called Centralite No. 1, is now more common; the methyl compound is now called Centralite No. 2.

The reaction of centralite with oxides of nitrogen has also been studied rather intensively, but opinion as to the nature of the reaction differs. One belief is that the reaction is simple nitration, forming first a dinitro compound with nitro groups substituted in the para positions of the two phenyl rings, and finally a tetranitro compound with two ortho and two para positions substituted (16). Another theory is that the centralite molecule is broken up, forming p-nitro phenyl ethyl

nitrosamine. (17) In either case, it should be noted that one centralite molecule takes up four nitro groups, which is one more than diphenylamine can absorb.

#### Other Compounds

Many other compounds have been used, or at least proposed, as stabilizers. Not much is known about the reactions they undergo, but a great many comparisons have been made as to the relative powers of stabilization. Some of the more important suggested substances are:

acardite (assymmetrical diphenyl urea)

alpha naphthyl urethane

camphor

carbazole

dianyl phthalate

diphenylbenzamide

ethyl oxinilate

mucic acid

naphthalene

nitro naphthalene

phenanthrene

potassium oxinilate

petrolatums of various kinds

phthalide

substituted urethanes

saccharic acid

tartaric acid

THE UNIVERSITY OF CHICAGO

1. The first step in the process of the investigation is to determine the scope of the problem. This involves identifying the specific areas of concern and the potential causes of the problem. Once the scope is defined, the next step is to gather data. This can be done through a variety of methods, including interviews, surveys, and observation. The data is then analyzed to identify patterns and trends. Finally, the results of the investigation are used to develop a plan of action to address the problem.

1947-1948 1949-1950 1951-1952 1953-1954 1955-1956 1957-1958 1959-1960 1961-1962 1963-1964 1965-1966 1967-1968 1969-1970 1971-1972 1973-1974 1975-1976 1977-1978 1979-1980 1981-1982 1983-1984 1985-1986 1987-1988 1989-1990 1991-1992 1993-1994 1995-1996 1997-1998 1999-2000 2001-2002 2003-2004 2005-2006 2007-2008 2009-2010 2011-2012 2013-2014 2015-2016 2017-2018 2019-2020 2021-2022 2023-2024 2025-2026 2027-2028 2029-2030 2031-2032 2033-2034 2035-2036 2037-2038 2039-2040 2041-2042 2043-2044 2045-2046 2047-2048 2049-2050 2051-2052 2053-2054 2055-2056 2057-2058 2059-2060 2061-2062 2063-2064 2065-2066 2067-2068 2069-2070 2071-2072 2073-2074 2075-2076 2077-2078 2079-2080 2081-2082 2083-2084 2085-2086 2087-2088 2089-2090 2091-2092 2093-2094 2095-2096 2097-2098 2099-2100 2101-2102 2103-2104 2105-2106 2107-2108 2109-2110 2111-2112 2113-2114 2115-2116 2117-2118 2119-2120 2121-2122 2123-2124 2125-2126 2127-2128 2129-2130 2131-2132 2133-2134 2135-2136 2137-2138 2139-2140 2141-2142 2143-2144 2145-2146 2147-2148 2149-2150 2151-2152 2153-2154 2155-2156 2157-2158 2159-2160 2161-2162 2163-2164 2165-2166 2167-2168 2169-2170 2171-2172 2173-2174 2175-2176 2177-2178 2179-2180 2181-2182 2183-2184 2185-2186 2187-2188 2189-2190 2191-2192 2193-2194 2195-2196 2197-2198 2199-2200 2201-2202 2203-2204 2205-2206 2207-2208 2209-2210 2211-2212 2213-2214 2215-2216 2217-2218 2219-2220 2221-2222 2223-2224 2225-2226 2227-2228 2229-2230 2231-2232 2233-2234 2235-2236 2237-2238 2239-2240 2241-2242 2243-2244 2245-2246 2247-2248 2249-2250 2251-2252 2253-2254 2255-2256 2257-2258 2259-2260 2261-2262 2263-2264 2265-2266 2267-2268 2269-2270 2271-2272 2273-2274 2275-2276 2277-2278 2279-2280 2281-2282 2283-2284 2285-2286 2287-2288 2289-2290 2291-2292 2293-2294 2295-2296 2297-2298 2299-2300 2301-2302 2303-2304 2305-2306 2307-2308 2309-2310 2311-2312 2313-2314 2315-2316 2317-2318 2319-2320 2321-2322 2323-2324 2325-2326 2327-2328 2329-2330 2331-2332 2333-2334 2335-2336 2337-2338 2339-2340 2341-2342 2343-2344 2345-2346 2347-2348 2349-2350 2351-2352 2353-2354 2355-2356 2357-2358 2359-2360 2361-2362 2363-2364 2365-2366 2367-2368 2369-2370 2371-2372 2373-2374 2375-2376 2377-2378 2379-2380 2381-2382 2383-2384 2385-2386 2387-2388 2389-2390 2391-2392 2393-2394 2395-2396 2397-2398 2399-2400 2401-2402 2403-2404 2405-2406 2407-2408 2409-2410 2411-2412 2413-2414 2415-2416 2417-2418 2419-2420 2421-2422 2423-2424 2425-2426 2427-2428 2429-2430 2431-2432 2433-2434 2435-2436 2437-2438 2439-2440 2441-2442 2443-2444 2445-2446 2447-2448 2449-2450 2451-2452 2453-2454 2455-2456 2457-2458 2459-2460 2461-2462 2463-2464 2465-2466 2467-2468 2469-2470 2471-2472 2473-2474 2475-2476 2477-2478 2479-2480 2481-2482 2483-2484 2485-2486 2487-2488 2489-2490 2491-2492 2493-2494 2495-2496 2497-2498 2499-2500 2501-2502 2503-2504 2505-2506 2507-2508 2509-2510 2511-2512 2513-2514 2515-2516 2517-2518 2519-2520 2521-2522 2523-2524 2525-2526 2527-2528 2529-2530 2531-2532 2533-2534 2535-2536 2537-2538 2539-2540 2541-2542 2543-2544 2545-2546 2547-2548 2549-2550 2551-2552 2553-2554 2555-2556 2557-2558 2559-2560 2561-2562 2563-2564 2565-2566 2567-2568 2569-2570 2571-2572 2573-2574 2575-2576 2577-2578 2579-2580 2581-2582 2583-2584 2585-2586 2587-2588 2589-2590 2591-2592 2593-2594 2595-2596 2597-2598 2599-2600 2601-2602 2603-2604 2605-2606 2607-2608 2609-2610 2611-2612 2613-2614 2615-2616 2617-2618 2619-2620 2621-2622 2623-2624 2625-2626 2627-2628 2629-2630 2631-2632 2633-2634 2635-2636 2637-2638 2639-2640 2641-2642 2643-2644 2645-2646 2647-2648 2649-2650 2651-2652 2653-2654 2655-2656 2657-2658 2659-2660 2661-2662 2663-2664 2665-2666 2667-2668 2669-2670 2671-2672 2673-2674 2675-2676 2677-2678 2679-2680 2681-2682 2683-2684 2685-2686 2687-2688 2689-2690 2691-2692 2693-2694 2695-2696 2697-2698 2699-2700 2701-2702 2703-2704 2705-2706 2707-2708 2709-2710 2711-2712 2713-2714 2715-2716 2717-2718 2719-2720 2721-2722 2723-2724 2725-2726 2727-2728 2729-2730 2731-2732 2733-2734 2735-2736 2737-2738 2739-2740 2741-2742 2743-2744 2745-2746 2747-2748 2749-2750 2751-2752 2753-2754 2755-2756 2757-2758 2759-2760 2761-2762 2763-2764 2765

triacetate of methyl trimethylol methane (18)

triphenylamine

### Comparison of Stabilizing Power

Many workers have made comparisons of the stabilizing power of various groups of the compounds listed above. However it is rather difficult to integrate the results, since methods differed widely and since each worker compared only a few compounds. The results of some of the more important experiments are given below:

Marqueyrol, in his work mentioned above, also made comparisons of the stabilizing power of several compounds. These included amyl alcohol, diphenylamine, nitronaphthalene, naphthalene, diphenyl benzamide, diphenyl nitrosamine, and carbazole. He, of course, concluded that diphenylamine was the best stabilizer, and it was his work that first promoted the use of this compound. However, he found that for some temperatures the benzamide was better, and he also found that carbazole, while not as good a stabilizer as diphenylamine, has less direct action on the nitrocellulose at high temperatures, and therefore can be used in larger quantities with safety.

Giua and Guastalla (19) ran comparative tests on several compounds. They concluded that the compounds under consideration could be arranged in order of decreasing stabilizing effect as follows:

Diphenylamine

Centralite

Aniline

alpha Naphthylurethane

Ethyl Oxinilate

Potassium Oxinilate

Phthalide

M. Tonegutti, (20) (21), found that diphenylamine and centralite were of equal power and were the best stabilizers of all he tested. Disubstituted urethanes were good stabilizers when mixed with acardite, but not alone, while phthalide and diamyl- and dibutyl-phthalates had no stabilizing action at all. Substances that are both stabilizers and gelatinizers gave very good results when mixed with substances which are stabilizers only, producing better stabilization than either substance used alone. Phenanthrene gave very good results on nitroglycerine powders. He concluded that diphenylamine is the best stabilizer for double-base powders, but acardite is the best for single-base powders.

Tonegutti also compared the stabilizing power of various petrolatums, since these were being seriously considered at that time. (22) As might be expected, it was found that those having the highest degree of unsaturation (as shown by the bromine number) were the best stabilizers.

R. Dalbert (23) compared powders containing 8.75 per cent of centralite with powders in which 2 per cent of the centralite had been replaced with either diphenylamine or carbazole. In each case, the straight centralite was the best,

the carbazole being the worst.

Dalbert also studied the action of triphenylamine as a stabilizer, comparing its action to that of diphenylamine. (24) Powders containing two and five per cent of triphenylamine were compared with similar powders containing diphenylamine. The two-per cent powders showed similar action when heated to 100° C. but powder containing five per cent of triphenylamine showed less denitration than the corresponding diphenylamine powder. No nitroso compound was formed from the triphenylamine, the first product being a mononitro compound. These tests seem to indicate that triphenylamine might make a superior stabilizer, but apparently no further work has been done towards confirming this.

Krauz and Majrach considered the action of di- and tri- carboxylic acids, using tartaric acid as typical. Tartaric acid took up two nitro groups, forming dinitro tartaric acid. This compound when heated in aqueous solution decomposed into carbon dioxide, nitrogen trioxide, nitrogen, and a small amount of carbonic acid. If heated dry, the gases varied with temperature, glyoxalic acid being left in the solid residue. (25)

The same two workers also studied the nitro esters of other dicarboxylic acids, namely glutaric, muic, and saccharic. These were found to act very much like tartaric acid, and to be better stabilizers than tartaric acid. (26)

Desmaroux (27) studied the comparative stabilising effects of camphor and centralite, and concluded that camphor was

[illegible]

as good as centralite, at least for periods up to 600 days, which was the longest test conducted.

#### Testing for Stability of Powder

No really satisfactory method of testing the stability of smokeless powder has as yet been devised. For research problems, such as comparing the stabilizing effect of various substances, the reduction in nitrogen content is taken as a measure of instability. Thus to compare two stabilizers, powders containing each are prepared, and rather large samples of each kept under carefully controlled conditions of temperature and humidity for a long time. From time to time, samples of each are withdrawn and analysed for nitrogen, the powder which has lost the least being considered the better stabilized. This method presents several difficulties and is really not very satisfactory. The nitrocellulose must be removed from the stabilizer and its products and tested for its nitrogen content. This presents difficulties and the method employed varies with the type of powder and the stabilizer. In addition, as has been mentioned before, the temperature plays an important part in the effective stability, some substances acting as very good stabilizers at one temperature but being very poor at other temperatures either higher or lower. Accordingly, such tests should be run at several temperatures.

Several methods have been used for testing stability without waiting for the actual decomposition to occur, as in the above tests. These are usually referred to as

in the above tests. These are usually referred to as stability tests for the actual decomposition of organic materials. Several methods have been used for testing stability in the case of organic materials. The most common method is the use of a constant temperature bath. The material is placed in a container and the container is placed in a bath of water or oil. The temperature of the bath is maintained at a constant value. The material is then removed from the bath and the weight loss is determined. This method is suitable for the study of the stability of organic materials in the case of decomposition. Another method is the use of a constant pressure bath. The material is placed in a container and the container is placed in a bath of water or oil. The pressure of the bath is maintained at a constant value. The material is then removed from the bath and the weight loss is determined. This method is suitable for the study of the stability of organic materials in the case of decomposition. A third method is the use of a constant volume bath. The material is placed in a container and the container is placed in a bath of water or oil. The volume of the bath is maintained at a constant value. The material is then removed from the bath and the weight loss is determined. This method is suitable for the study of the stability of organic materials in the case of decomposition. A fourth method is the use of a constant weight bath. The material is placed in a container and the container is placed in a bath of water or oil. The weight of the bath is maintained at a constant value. The material is then removed from the bath and the weight loss is determined. This method is suitable for the study of the stability of organic materials in the case of decomposition. A fifth method is the use of a constant composition bath. The material is placed in a container and the container is placed in a bath of water or oil. The composition of the bath is maintained at a constant value. The material is then removed from the bath and the weight loss is determined. This method is suitable for the study of the stability of organic materials in the case of decomposition. A sixth method is the use of a constant pH bath. The material is placed in a container and the container is placed in a bath of water or oil. The pH of the bath is maintained at a constant value. The material is then removed from the bath and the weight loss is determined. This method is suitable for the study of the stability of organic materials in the case of decomposition. A seventh method is the use of a constant ionic strength bath. The material is placed in a container and the container is placed in a bath of water or oil. The ionic strength of the bath is maintained at a constant value. The material is then removed from the bath and the weight loss is determined. This method is suitable for the study of the stability of organic materials in the case of decomposition. A eighth method is the use of a constant dielectric constant bath. The material is placed in a container and the container is placed in a bath of water or oil. The dielectric constant of the bath is maintained at a constant value. The material is then removed from the bath and the weight loss is determined. This method is suitable for the study of the stability of organic materials in the case of decomposition. A ninth method is the use of a constant refractive index bath. The material is placed in a container and the container is placed in a bath of water or oil. The refractive index of the bath is maintained at a constant value. The material is then removed from the bath and the weight loss is determined. This method is suitable for the study of the stability of organic materials in the case of decomposition. A tenth method is the use of a constant viscosity bath. The material is placed in a container and the container is placed in a bath of water or oil. The viscosity of the bath is maintained at a constant value. The material is then removed from the bath and the weight loss is determined. This method is suitable for the study of the stability of organic materials in the case of decomposition.

"heat tests". The two most common of these in this country are the 65.5° C. KI starch test and the 134.5° C. methyl violet test.

In the KI starch test, the powder samples are heated in test tubes at 65.5° C. Within each tube, a strip of KI starch paper, spotted with a 50 per cent aqueous solution of glycerine, is hung from a platinum hook. The tubes are stoppered with cork. The tubes are examined constantly and the time required for the first appearance of color on the paper is reported. Specifications in the United States call for at least 35 minutes before the first appearance of color.

In the methyl violet test, long tubes of heavy glass are used. They are closed loosely with notched corks, and are heated for almost their whole length in a bath at 134.5° C. The sample occupies about two inches of the lower end of the tube, and strips of methyl violet paper are placed about one inch above the sample. Times are noted for the paper to be turned completely to a salmon-pink color, for the first appearance of red fumes, and for explosion. Explosion usually does not occur for about five hours.

It will be noted that neither of the above gives a true indication of stability, since they measure the time for the self-catalyzed reaction in an atmosphere of air or red fumes. They thus serve only to compare the stability of powders which are similar in other respects. For true observations of stability, a heat test under vacuum is necessary.

[illegible]

### Effects of Temperature and Humidity on Stability

If smokeless powder is exposed to a humid atmosphere, it will absorb moisture slowly. Conversely, it will give up moisture to a dry atmosphere. The extent of both of these is dependent on the amount of surface moisture present originally in the powder, as mentioned above. The hygroscopicity also seems to depend on the total amount of nitrocellulose present, so that double base powders are less hygroscopic than straight nitrocellulose powder.

The amount of moisture present has a very marked effect on the stability. In one experiment a powder was exposed to a saturated atmosphere for three months at 50° C. After this exposure, it was kept at 65.5° C. in a closed container, red fumes appearing after nine days. The same powder, unexposed to the humid atmosphere, took 540 days to produce red fumes under the same conditions. (28)

Changes in temperature and humidity affect the stability of powder in another fashion, also. As the powder takes up moisture, the water and volatile matter in the powder move inward from the surface toward the interior. If the same powder then loses water, due to a change in conditions, this water moves outward. Thus there is a constant shifting of the liquid within the powder. This tends to break up the structure of the grain and promote decomposition.

Smokeless powder deteriorates much more rapidly at high than at low temperatures. This is due partly to the

at high than at low temperature. This is due partly to the fact that the rate of decomposition is much more rapid at high than at low temperature. This is due partly to the fact that the rate of decomposition is much more rapid at high than at low temperature.

acceleration of the decomposition reaction of nitrocellulose and partly to the fact that the stabilizer also decomposes at high temperatures. Diphenylnitrosamine decomposes very easily as the temperature is raised, and hence the stability of diphenylamine powders decreases rapidly.

1. The first of these is the question of the origin of the disease.

2. The second is the question of the mode of transmission.

3. The third is the question of the clinical picture of the disease.

4. The fourth is the question of the treatment of the disease.

5. The fifth is the question of the prognosis of the disease.

6. The sixth is the question of the prevention of the disease.

7. The seventh is the question of the epidemiology of the disease.

8. The eighth is the question of the pathology of the disease.

9. The ninth is the question of the histology of the disease.

10. The tenth is the question of the immunology of the disease.

11. The eleventh is the question of the bacteriology of the disease.

12. The twelfth is the question of the virology of the disease.

13. The thirteenth is the question of the parasitology of the disease.

14. The fourteenth is the question of the entomology of the disease.

15. The fifteenth is the question of the zoology of the disease.

16. The sixteenth is the question of the botany of the disease.

17. The seventeenth is the question of the geology of the disease.

18. The eighteenth is the question of the meteorology of the disease.

19. The nineteenth is the question of the climatology of the disease.

20. The twentieth is the question of the astronomy of the disease.

21. The twenty-first is the question of the physics of the disease.

22. The twenty-second is the question of the chemistry of the disease.

23. The twenty-third is the question of the mathematics of the disease.

24. The twenty-fourth is the question of the logic of the disease.

25. The twenty-fifth is the question of the metaphysics of the disease.
